The 26S proteasome is the major protein degradative machinery of the cell and is regulated at many levels. One mode of regulation involves accumulation of proteasomes in proteasome storage granules (PSGs) upon glucose depletion. Using a systematic robotic screening approach in yeast, we identify trans-acting proteins that regulate the accumulation of proteasomes in PSGs. Our dataset was enriched for subunits of the vacuolar adenosine triphosphatase (V-ATPase) complex, a proton pump required for vacuole acidification.

We show that the impaired ability of V-ATPase mutants to properly govern intracellular pH affects the kinetics of PSG formation. We further show that formation of other protein aggregates upon carbon depletion also is triggered in mutants with impaired activity of the plasma membrane proton pump and the V-ATPase complex. We thus identify cytosolic pH as a specific cellular signal involved both in the glucose sensing that mediates PSG formation and in a more general mechanism for signaling carbon source exhaustion.

Introduction

The 26S proteasome is a 2.5-MD protease that is composed of the 19S regulatory particle (RP) and the 20S core particle (CP), which possesses the protease activity. In eukaryotes, the major mechanism for targeting proteins to the proteasome is through the process of ubiquitination. Through this pathway the ubiquitin–proteasome system exerts its influence by selectively degrading misfolded, damaged, or regulatory proteins (Hershko and Ciechanover, 1998).

Proteolytic function must be tightly regulated in a cellular environment, and therefore, mechanisms exist to turn the proteasome off. This massive complex is highly abundant (~1% of the yeast proteome; Russell et al., 1999) and therefore costly to synthesize and assemble. Therefore, degradation can be considered to be the least favored regulation in this case. The alternate option, that is widely used, is to assemble it into proteasome storage granules (PSGs) during cellular stress conditions such as glucose starvation or quiescence (Laporte et al., 2008). In these conditions, nonselective autophagy is activated in yeast cells, and it is thought that the PSGs represent a protective mechanism that shelters the proteasome from autophagic degradation.

The utilization of PSGs enables cells to avoid the replenishment of large amounts of active proteasome subunits and the possible delay in reentry into the proliferative state. In fact, many other proteins that are localized diffusely in the cytoplasm can be catabolized through the glycolytic pathway to exert this effect (Daignan-Fornier and Sagot, 2011; Laporte et al., 2011). Still, it is not clear which metabolite resulting from glucose catabolism is required for glucose induced cytoplasmic granule mobilization.

In this paper, we describe a whole-genome systematic screening approach that allowed us to discover mutants that affect the shuttling of the proteasome into PSGs (Fig. 1 A). The functional distribution of the identified mutants reveals enrichment for subunits of the vacuolar ATPase (V-ATPase; Table 1). We show that...
in the cytosol and nucleus. Therefore, we set out to uncover additional factors that regulate this process. To visually screen for such factors, we first created a yeast strain (based on the yeast S288C background; Brachmann et al., 1998) expressing a fluoroscently tagged RP proteasome subunit (Rpn5-GFP). Indeed, as expected, this fusion protein localized correctly to both the cytosol and the nucleus (Fig. 1 B, wt). Using synthetic genetic array (SGA) methodology (Tong and Boone, 2006; Cohen and Schuldiner, 2011), we crossed this strain against the yeast deletion library (Giaever et al., 2002), which consists of \( \approx 5,000 \) strains, each harboring a deletion in one nonessential gene. This procedure allowed us to create a library of nearly 5,000 haploid cells, each expressing the Rpn5-GFP fusion protein on the background of a mutation in a single gene (Fig. 1 A). The freshly grown colonies were copied from agar plates into liquid cultures in synthetic medium containing glucose (synthetic defined [SD]) for overnight growth. After back dilution into fresh medium for the kinetics of PSG formation in the mutants upon carbon depletion is different from that seen in the wild type (wt), probably because of the impaired ability of the V-ATPase mutants to properly adjust their intracellular pH (pHi), in response to carbon starvation. Further characterization identified cytosolic pH as a novel regulator that mediates the formation of PSGs and other protein aggregates that form upon sugar depletion. We therefore propose that cytosolic pH acts as the cellular signal for glucose sensing and mediates the formation of PSGs in response to carbon depletion.

Results and discussion

A systematic approach for the identification of trans-acting proteins regulating proteasome sequestering into PSGs

The regulation of proper partitioning of the proteasome into PSGs is essential for maintaining the correct level of the proteasome in the cytosol and nucleus. Therefore, we set out to uncover additional factors that regulate this process. To visually screen for such factors, we first created a yeast strain (based on the yeast S288C background; Brachmann et al., 1998) expressing a fluoro-escently tagged RP proteasome subunit (Rpn5-GFP). Indeed, as expected, this fusion protein localized correctly to both the cytosol and the nucleus (Fig. 1 B, wt). Using synthetic genetic array (SGA) methodology (Tong and Boone, 2006; Cohen and Schuldiner, 2011), we crossed this strain against the yeast deletion library (Giaever et al., 2002), which consists of \( \approx 5,000 \) strains, each harboring a deletion in one nonessential gene. This procedure allowed us to create a library of nearly 5,000 haploid cells, each expressing the Rpn5-GFP fusion protein on the background of a mutation in a single gene (Fig. 1 A). The freshly grown colonies were copied from agar plates into liquid cultures in synthetic medium containing glucose (synthetic defined [SD]) for overnight growth. After back dilution into fresh medium for

Figure 1. A systematic approach for the identification of trans-acting proteins regulating proteasome sequestering into PSGs. (A) To uncover novel regulators of proteasome localization into PSGs, we integrated Rpn5-GFP into every strain of the yeast deletion collection (1), resulting in a systematic library harboring the tagged proteasome on the background of single gene deletions (2). After high content screening (3), we manually categorized the localization of Rpn5-GFP for all strains tested (4) and recognized hits. (B) Deletion of V-ATPase subunits results in proteasome failure to leave PSGs during logarithmic growth. Representative images of data acquired during the systematic screening approach described in A. Although Rpn5-GFP accumulates in the nucleus in the control cells (wt), it is still found in PSGs in cells deleted for V-ATPase subunits (pointed to by a white arrow in vma22 mutant) despite the abundance of glucose. Bar, 5 µm.
In the majority of the cases, cells responded as expected to the increase in glucose levels (caused during the back dilution into fresh medium) and relocated their proteasomes from PSGs back into the cytosol and the nucleus. However, the time of recovery in 11 mutants was significantly delayed, enabling us to identify genes that abrogate the ability of cells to sense the changes in glucose levels and respond properly by releasing proteasomes from PSGs (Table 1). Interestingly, the functional distribution of the identified mutants reveals that our data were highly enriched for genes that govern pH. These genes include seven subunits of the V-ATPase complex and one subunit required for its assembly (Table 1).

Impaired ability of V-ATPase mutants to control pH significantly affects the redistribution of the proteasome from PSGs

V-ATPase, a proton pump required for the acidification of vacuoles, plays a central role in vacuolar and cytosolic pH homeostasis in all eukaryotic cells. V-ATPases are activated by glucose and function together with Pma1 to pump protons out of the cytosol to help regulate cytosolic pH. Reduction in cytosolic pH as a result of glucose deprivation is necessary for the inactivation of V-ATPase by their reversible disassembly (Dechant et al., 2010). In V-ATPase mutants, even at optimal extracellular pH, cytosolic pH was previously shown to be much lower, and cells failed to respond properly when glucose was added (Dechant et al., 2010; Young et al., 2010). Given that it is known that PSGs are regulated by glucose availability, we were intrigued by the idea that V-ATPase function could be the missing link between glucose levels and signaling of PSG formation.

Because the screen was performed at a single time point and measured mostly the dissociation of PSGs, we decided to look at the effect of V-ATPase mutants on the kinetics of PSGs formation. We focused on a representative mutant, Δvma2 and followed the localization of Rpn5-GFP after depletion of glucose relative to control (wt) cells. At t = 0, Rpn5-GFP localized to the nucleus both in wt and Δvma2 mutants (Fig. 2 A, t = 0). Resuspension of wt cells in glucose-free synthetic media (synthetic complete [SC]) led to the expected relocation of Rpn5-GFP to PSGs in 87% of the cells within 24 h. Strikingly, in Δvma2 cells, the kinetics of PSGs formation was significantly faster with 44% of the cells displaying Rpn5-GFP localization to the nuclear periphery after 1 h and 72% of the cells displaying PSGs after 4 h. Furthermore, as expected from the phenotypes observed in our screen, the kinetics of Rpn5-GFP disassembly and relocalization back into the nucleus in response to glucose replenishment was significantly slower in Δvma2 mutants (Fig. 2 A, +Dex; the full kinetics of disassembly and relocalization is shown in Fig. S1 C). Similar kinetics were obtained with cells mutated in another V-ATPase subunit (Δvma5; Fig. S1 D), with the CP protein Pup2 fused to GFP (Fig. 2 B), and with cells treated with the V-ATPase–specific inhibitor concanamycin A (Fig. S1 E; Krogan et al., 2004; Dechant et al., 2010). We also verified that Pup2 (tagged with mCherry) and Rpn5 (tagged with GFP) colocalize in the PSGs formed in Δvma2 to ensure that this mutation did not create a change in PSG physiology (Fig. S1 F). Collectively, these results suggest that the impaired ability to control pH in V-ATPase mutants increased the sensitivity of cells to lower levels of the carbon source and induced the simultaneous relocalization of both core and regulatory proteasomal subunits into PSGs (Fig. 2).

Rapid drop of internal pH is sufficient for formation of PSGs at constant glucose levels

Our screen identified that mutated subunits of V-ATPase, key regulators of pH homeostasis, affect the kinetics of PSGs formation. Previous studies have shown that glucose-starved yeast exhibit a rapid drop in pH (Martínez-Muñoz and Kane, 2008; Dechant et al., 2010; Young et al., 2010). Because both glucose-starved yeast and mutants that control pH (Fig. 2) affect the formation of PSGs, we hypothesized that the internal drop in cytosolic pH might be the physiological signal for PSG formation. To test this hypothesis, we assayed whether changes in pH are sufficient to mediate the formation of PSGs, even when glucose levels are kept high (2%).

First, we analyzed the localization of Rpn5-GFP at timely intervals, after cells were shifted to dextrose-containing buffers, buffered to normal and low pH (pH 7.5 and 4.0, respectively). The buffers also contained the proton ionophore carbonyl cyanide 3-chlorophenylhydrazone (CCCP), which affects the plasma membrane proton gradient and therefore prevents cells from controlling their internal pH (Orij et al., 2009). The results clearly show that after 120 min, under normal pH (7.5), the GFP signal was mainly localized to the nucleus (~63% of the cells) and, in ~30% of the cells, to the nuclear periphery (Fig. 3, A [top] and B). In contrast, at a lower pH, the proteasome formed PSGs in 55% of the cells (Fig. 3 A, bottom, white arrow) and relocalized to the nuclear periphery in the others. When the cells were shifted back to physiological pH and allowed to recover in the presence of dextrose + CCCP, the GFP signal in most cells relocated back into the nucleus within 30 min (Fig. 3 A, right). Furthermore, the PSGs formed after 24 h in minimal medium (Fig. 3 C, left) relocalized back into nucleus (in 95% of the cells) when cells were resuspended in a medium adjusted to pH 7.5, supplemented with CCCP and glucose (Fig. 3 C, middle). In contrast, relocalization was impaired when cells were resuspended in a similar medium that was buffered to a low pH (4.0; Fig. 3 C, right).

Next, we decided to test the effect of physiological changes in pH by analyzing the localization of Rpn5-GFP on cells expressing reduced levels of Pma1. It has been previously shown that in wt cells, in response to glucose starvation, Pma1 is repressed, resulting in a rapid drop in pH (Fig. 4 A, left and middle; Young et al., 2010). pma1-007 is a hypomorphic allele of PMA1 that was previously shown to reduce the activity...
of PSG formation was significantly higher in pma1-007 mutants, with 31% of the cells forming PSGs in the mutants, \( n = 210 \) versus only 8% in the control, \( n = 204 \); Fig. 4, B and C).

Under these conditions, the proteasome CP subunit Pre6-mCherry was similarly affected and clearly colocalized with the Rpn5-GFP (Fig. S2 A). To further support these results, we transferred}

of the Pma1 protein by 50% (Porat et al., 2005; Young et al., 2010). This results in a decreased capacity to pump protons out of the cell and a concomitant reduction in cytosolic pH, similar to that which occurs when CCCP is added externally (Fig. 4 A, right). The results clearly show that although both strains were grown in glucose-rich medium for 30 h, the rate of PSG formation was significantly higher in pma1-007 mutants, with 31% of the cells forming PSGs in the mutants, \( n = 210 \) versus only 8% in the control, \( n = 204 \); Fig. 4, B and C). Under these conditions, the proteasome CP subunit Pre6-mCherry was similarly affected and clearly colocalized with the Rpn5-GFP (Fig. S2 A). To further support these results, we transferred

Figure 2. The kinetics of PSG formation is affected in cells deleted in V-ATPase subunit VMA2 (Δvma2). (A and B) Logarithmic wt and Δvma2 cells expressing the lid subunit Rpn5-GFP (A) and the core subunit Pup2-GFP (B) were washed and resuspended in glucose-free medium [t = 0] for 24 h and then transferred back into a glucose-rich medium [+dextrose [+DEX]]. Cells were visualized by differential interference contrast (DIC) and GFP at the indicated time points. The localization of Rpn5-GFP (A) and Pup2-GFP (B) was scored as nuclear, nuclear periphery (N.P), or PSGs. Unless otherwise stated, the representative images in all figures show the dominant localization pattern for each of the indicated time points. For each time point, a minimum of 200 cells was counted (\( n > 200 \)); error bars show the standard deviation between two independent experiments. Bars, 5 \( \mu \)m. Images represent high resolution (63×) images of a single plane chosen from z series images extending above and below the entire cell.
In total, these results strongly suggest that the rapid drop in pHi and the acidification of the cytosol (either by external treatment with CCCP or genetically by reducing Pma1 levels) are sufficient to trigger PSG formation. Overall, our findings demonstrate for the first time that the change in cytosolic pH in response to glucose levels serves as a messenger and a major cellular signal to mediate the activation of PSGs reorganization.

pH homeostasis is critical for the survival of yeast cells, as it is for all eukaryotic cells. Indeed, as expected, previous studies have shown a link between cytosolic pH and various cellular activities. For example, Young et al., 2010 have demonstrated a link between nutrient availability, pH biosensing, and membrane biogenesis. A very recent study identified that an early age increase in vacuolar pH limits mitochondrial function and life span in yeast (Hughes and Gottschling, 2012). Other work has shown that the increase in cytosolic pH as a result of addition of glucose in starved cells promotes V-ATPase assembly and that this activation positively regulates the cAMP-dependent PKA pathway in yeast (Dechant et al., 2010). Similarly, our study demonstrated that reducing pHi in control cells, and to a greater extent in pma1-007 mutants, when compared with SD. As expected, under such conditions, the kinetics of PSGs formation were dramatically faster and were detected after 4 h, with 62% of the cells exhibiting PSGs in the mutants, (n = 200) versus 18% in the control (n = 200; Fig. S2 B). Furthermore, we have repeated the experiment described in Fig. 4 A, this time in the presence of 100 µM ebselen, both in wt cells and pma1-007 mutants. A previous study has shown that the drug ebselen inhibits Pma1 in vitro and causes an immediate drop in internal pHi of both wt and pma1-007 cells to ~6.3. Whereas wt cells stabilized at pHi ~6.4, pHi of pma1-007 cells continued to decrease (Chan et al., 2007). As expected from the immediate drop in internal pHi, we have observed that the addition of ebselen resulted in faster kinetics of nuclear periphery and PSG formation in pma1-007 cells, indicating that the mutant is more sensitive, likely as a result of reduced gene dosage (Fig. S2 C).

Figure 3. Failure to control internal pH affects PSG formation. [A] Logarithmically growing culture (untreated), expressing the lid subunit Rpn5-GFP, was washed and resuspended in glucose (dextrose [Dex]-containing buffers, buffered to physiological pHi, pH 7.5 (control), and to pH 4.0, supplemented with CCCP. Both samples were then washed and allowed to recover for 30 min in pH 7.5 +CCCP (Recovery). Cells were visualized by DIC and GFP at the indicated time points. The localization of Rpn5-GFP was scored as described in Fig. 2. PSGs are pointed out by a white arrow. (B) Representative images in all figures show the dominant localization pattern for each of the indicated time points. Error bars show the standard deviation between two independent experiments. (C) Similar experimental setup as was described in A, this time, PSG relocalization in cells grown in a low glucose media for 24 h (24 h in SC) was examined after the resuspension in the indicated medium [CCCP + dextrose]. N.P, nuclear periphery. Bars, 5 µm.

In total, these results strongly suggest that the rapid drop in pHi and the acidification of the cytosol (either by external treatment with CCCP or genetically by reducing Pma1 levels) are sufficient to trigger PSG formation. Overall, our findings demonstrate for the first time that the change in cytosolic pH in response to glucose levels serves as a messenger and a major cellular signal to mediate the activation of PSGs reorganization. pH homeostasis is critical for the survival of yeast cells, as it is for all eukaryotic cells. Indeed, as expected, previous studies have shown a link between cytosolic pH and various cellular activities. For example, Young et al., 2010 have demonstrated a link between nutrient availability, pH biosensing, and membrane biogenesis. A very recent study identified that an early age increase in vacuolar pH limits mitochondrial function and life span in yeast (Hughes and Gottschling, 2012). Other work has shown that the increase in cytosolic pH as a result of addition of glucose in starved cells promotes V-ATPase assembly and that this activation positively regulates the cAMP-dependent PKA pathway in yeast (Dechant et al., 2010). Similarly, our study
Figure 4. Impaired capacity to pump protons out of cells affects the kinetics of PSG formation. (A) Schematic illustration of PMA1 regulation. (B) pma1-007 and wt cells were grown in SD for 30 h. Cells were visualized by DIC and GFP at the indicated time points. The representative images shown at t = 30 h show the PSG localization pattern that was significantly enriched in pma1-007 mutants, comparing with the nuclear localization pattern that still appeared in wt cells. Bar, 5 μm. (C) Cells were visualized by DIC and GFP at the indicated time points. The localization of Rpn5-GFP was scored as described in Fig. 2. Error bars show the standard deviation between two independent experiments. N.P., nuclear periphery.

These results suggest that, similar to PSGs, the effect on Hos2-GFP in pma1-007 and Δvma2 mutants is the result of low cytosolic pH (Fig. S2 D).

Collectively, the relocalization of actin cytoskeleton and Hos2 suggests that cytosolic acidification represents a general signal that affects not only PSG formation but more broadly may be the signal for cytosolic protein relocalization in response to carbon source exhaustion. Cytosolic pH is regulated not only by glucose but also by other fermentable carbon sources (Dechant et al., 2010). This suggests that the yeast cell may use cytosolic pH as a downstream reporter on the availability of various carbon sources and enables cells to avoid monitoring the abundance of a specific carbon source or metabolite.

Materials and methods

Yeast strains and growth conditions

All the strains used in this study are isogenic to BY4741, BY4742, or BY4743 (Brachmann et al., 1998). The relevant genotypes are presented in Table S1. Gene deletions, GFP, and mCherry fusions were performed using one-step PCR-mediated homologous recombination (Longtine et al., 1998; Goldstein and McCusker, 1999). For all deletions, the selection markers replaced the coding region of the targeted genes. GFP and mCherry were fused at the 3′ of the coding region of the targeted genes, by replacing their stop codons. pma1-007 strain was a gift from C. Lowen’s laboratory (University of British Columbia, Vancouver, British Columbia, Canada). In this strain, insertion of the KanMX selection marker upstream of the coding region of PMA1 resulted in reduced activity of the Pma1 protein by 50%. We have verified that the proteasome is expressed at the same level in wt and in the mutants used in this study (Δvma2, pma1-007, and Δvma5; Fig. S1 A). We also show that the expression of the fusion proteins Rpn5-GFP, Pup2-GFP, and Pre6-mCherry have no effect on proteasome activity (Fig. S1 B).

Yeast cells were grown in synthetic medium (SD; 0.17% yeast nitrogen base, 0.5% (NH₄)₂SO₄, 2% glucose, and amino acids). Glucose starvation was performed in SC (SD without glucose). Unless stated otherwise, the pH of the synthetic media was buffered to pH 4.6. Yeast cells were grown in liquid medium at 30°C in glass tubes. For logarithmic culture, yeast cells were grown for 16–18 h and then back diluted 10× with fresh media and allowed to grow for 2 h. For glucose starvation experiments, strains were grown in medium containing 2% glucose to logarithmic phase, collected by centrifugation, washed once, and resuspended in the same medium lacking glucose.

suggested that the reformation of PSGs is also mediated by V-ATPase reassembly and that the V-ATPase complex functions as an intracellular glucose sentinel. Failure of the VMA mutants to sense the changes in glucose levels misregulates cytosolic pH levels and leads to reduced efficiency of PSGs dynamics.

Drop in pH affects additional starvation markers

Previous studies have shown that many diffusely localized cytosolic proteins relocalize into cytoplasmic foci, such as PSGs or actin bodies upon carbon exhaustion (Sagot et al., 2006; Laporte et al., 2008). Because we observed that drop in pH as a result of carbon source exhaustion triggers the formation of PSGs, we wanted to test whether pH mediates the signal for a larger spectrum of cellular reprogramming that takes place upon glucose deprivation. To test this idea, we asked whether pma1-007 mutants also affected changes in actin structure. Indeed, after 8 h in SD, when the proteasomes are still localized into the nucleus, actin cables and patches were polarized in structures similar to those previously described in proliferating cells in 92% of the cells (Fig. 5, A and C; Pryne et al., 2004). In contrast, after 30 h, when PSGs appeared in 40% of the cells as a result of drop in pH, the actin cytoskeleton reorganized into structures typical of cells exposed to low carbon source (Sagot et al., 2006), including 65% showing depolarization of actin patches and 31% that formed actin bodies (Fig. 5, B and C). The kinetics of actin cytoskeleton reorganization is shown in Fig. 5 C. Similarly, using a stationary-phase granule (SPG) marker, Hos2-GFP (Liu et al., 2012), we found increased formation of SPGs both in pma1-007 and in Δvma2 mutants (Fig. 5, D and E). Similar results were obtained when we analyzed the localization of Hos2-GFP 120 min after cells were shifted to CCCP-containing buffers (similar to the experiment described in Fig. 3 A). The results clearly show that after 120 min, under normal pH (7.5), the GFP signal was mainly localized to nucleus (~75% of the cells). In contrast, at a lower pH, Hos2-GFP localized to the nuclear periphery or formed SPGs in 76% of the cells.
CCCP treatment

CCCP treatment was performed as previously described [Orij et al., 2009]. In brief, cells were reincubated at an OD_{600nm} of 0.6–1 to Heps buffer (25 mM Hepes, pH 7.4, 200 mM KCl, 1 mM CaCl_2, and 2% dextrose, pH 4.0 and 7.5) in the presence of 100 µM CCCP [Sigma-Aldrich].

Actin staining

Actin staining with phalloidin was performed as previously described [Sagot et al., 2006]. In brief, cells were fixed with formaldehyde (3.7% final), washed, and stained overnight with Alexa Fluor 568–phalloidin (Invitrogen). Cells were then washed twice, resuspended in a mounting solution containing 70% glycerol and 5 mg/liter paraphenylenediamine, and imaged at room temperature.

Microscopy

Cells were observed in a fully automated inverted microscope (Axio Observer.Z1; Carl Zeiss) equipped with an automated stage (MS-2000; Applied Scientific Instrumentation), a 300-W xenon light source (Lambda DG-4 LS; Sutter Instrument), a 63× oil, 1.4 NA Plan Apochromat objective lens, and a six-position filter cube turret with a GFP filter (excitation, bp...
